## Abstract

*Introduction:* Fructose, alone or in combination with glucose, has been used as a source of added sugars to manufacture sugary drinks and processed foods. High consumption of simple sugars, mainly fructose, has been demonstrated to be one of the causes of developing metabolic diseases. Maternal nutrition is a key factor in the health of the progeny when adult. However, ingestion of fructose-containing foods is still permitted during gestation. Hydrogen sulfide (H<sub>2</sub>S) is a gasotransmitter produced in the transsulfuration pathway with proved beneficial effects to fight metabolic diseases.

*Methods:* Therefore, maternal intake of liquid carbohydrates (glucose or fructose) and its effect in H<sub>2</sub>S production both in the offspring and in the response of the progeny to a fructose supplementation were studied.

*Results:* This study shows how in pregnancy, either a fructose-rich diet *per se* or situations that produce an impaired insulin sensitivity such an excessive intake of glucose, decrease hepatic and placental production of H<sub>2</sub>S. Further, this effect was also observed in liver of male offspring (both in fetal and adult stages). Interestingly, when these adult descendants were subjected to a high fructose intake, diminutions in H<sub>2</sub>S synthesis in liver and adipose tissue due to this fructose intake were maternal consumption dependent.

*Conclusions:* Given H<sub>2</sub>S is a protective agent against diseases such as diabetes, obesity, cardiovascular diseases and metabolic syndrome, the fact that carbohydrate consumption reduces H<sub>2</sub>S synthesis both in pregnancy and in their progeny would have clear and relevant clinical implications.

## Resumen

### **La ingesta de carbohidratos en forma líquida modifica la ruta de la transulfuración tanto en ratas gestantes como en su descendencia macho**

*Introducción:* La fructosa, sola o en combinación con glucosa, se usa como fuente de azúcares añadidos para elaborar bebidas azucaradas y comidas procesadas. El elevado consumo de azúcares simples, sobre todo fructosa, se ha mostrado como una de las causas del desarrollo de enfermedades metabólicas. La nutrición materna es un factor clave en la salud de la descendencia adulta. Sin embargo, el consumo de alimentos que contienen fructosa está todavía permitido durante la gestación. El sulfuro de hidrógeno ( $H_2S$ ) es un gasotransmisor producido en la ruta de la transulfuración con probados beneficios para luchar contra las enfermedades metabólicas.

*Métodos:* Por lo tanto, estudiamos la ingestión de carbohidratos líquidos (glucosa o fructosa) y su efecto en la producción de  $H_2S$  tanto en la descendencia como en la respuesta de ésta a una sobrecarga de fructosa.

*Resultados:* Este estudio muestra cómo en la gestación, una dieta rica en fructosa *per se* o situaciones en las que se produce una empeorada sensibilidad a la insulina tal como un consumo excesivo de glucosa, disminuyen la producción hepática y placentaria de  $H_2S$ . Más aún, este efecto también fue observado en el hígado de la descendencia macho (tanto en el estado fetal como en la edad adulta). Es destacable que, cuando esta descendencia adulta era sometida a una ingesta elevada de fructosa, las disminuciones en la síntesis de  $H_2S$  en hígado y tejido adiposo debidas a dicho consumo de fructosa eran dependientes del consumo materno.

*Conclusiones:* Dado que el  $H_2S$  es un agente protector contra enfermedades tales como la diabetes, la obesidad, enfermedades cardiovasculares y el síndrome metabólico, el hecho de que el consumo de carbohidratos reduzca la síntesis de  $H_2S$  tanto en la gestación como en su descendencia tendría claras implicaciones clínicas.

## 1. Introduction

Changes in food patterns and unhealthy diets are the main causes of the rising cases of metabolic syndrome (MetS), obesity and non-alcoholic fatty liver disease (NAFLD) all around the world, the excessive intake of sugar-sweetened beverages (SSB) being one of the main sources (1). Fructose is used as a source of added sugar in the form of High Fructose Corn Syrup (HFCS) and sucrose and a close relationship between its consumption and higher risk of suffering cardiometabolic risk factors has been established (2). Moreover, according to Developmental Origins of Health and Disease (DOHaD) theory, the mother's diet during pregnancy plays a key role in the correct development of the offspring when adult, mainly due to epigenetic changes (3). Indeed, many studies (including some ours) have established an association between fructose intake during pregnancy and detrimental effects in the fetuses and adult descendants (4, 5). We have previously seen features of MetS in male, but not female, offspring from fructose fed mothers, such as an impaired insulin signaling, hypoadiponectinemia and steatosis (6). Thus, although a connection between a high consumption of fructose containing beverages and the global epidemic of obesity and metabolic syndrome could exist (5, 7), ingestion of these beverages and fruit juices is still permitted during gestation.

Metabolism is regulated by different chemical species, but only three of them are gasotransmitters: nitric oxide (NO), carbon monoxide (CO), and hydrogen sulfide (H<sub>2</sub>S). They are produced enzymatically, are able to cross the cell membrane by simple diffusion and to modulate cellular function (8). Among them, H<sub>2</sub>S has increased its relevance in the last years due to its emerging role in cardiovascular diseases, due to its anti-inflammatory, antioxidant and vasodilatory effects (9). This gasotransmitter is synthesized in the transsulfuration pathway in many organs such as liver, kidney, heart and adipose tissue. There are three main enzymes involved in its formation: cystathionine beta-synthase (CBS), cystathionine gamma-lyase (CSE), which work in concert to transform Homocysteine (HCy) into H<sub>2</sub>S, and 3-mercaptopyruvate sulfurtransferase (3-MST) which uses mercaptopyruvate to produce H<sub>2</sub>S (8). Diminutions in H<sub>2</sub>S levels and lower expression of transsulfuration enzymes have been linked to an impaired insulin sensitivity in adipose tissue (10). In the liver, H<sub>2</sub>S donor administration

has been demonstrated to decrease liver steatosis by a reduction of lipid production and an activation of the antioxidant systems activity in mice treated with a High-Fat Diet (11). However, some studies have shown increases in CSE expression and H<sub>2</sub>S production in insulin resistance animal models (12). Interestingly, H<sub>2</sub>S has been proved to have beneficial effects in cardiovascular diseases (CVD). It works as a cardioprotective factor by reducing oxidative stress, inflammation, fibrosis and apoptosis (13, 14). Taking into account all these effects of H<sub>2</sub>S, some authors have proposed it as a novel agent for therapy for hypertension, atherosclerosis, myocardial hypertrophy and heart failure by administering sulfur donors or increasing endogenous H<sub>2</sub>S production (15).

Not many studies have evaluated the transsulfuration pathway after fructose intake and, even fewer, if the DOHaD theory could be involved. Therefore, we have investigated here whether maternal liquid fructose (10% wt/vol in drinking water) intake affects this pathway in pregnant rats and their fetuses, and if it differs from glucose consumption (10% wt/vol in drinking water) or water without additives (control). In addition, in order to study a possible fetal programming, the H<sub>2</sub>S production in several tissues was measured in adult male offspring of mothers having consumed different carbohydrates. Subsequently, we wanted to know if males whose mothers had consumed water without additive, fructose or glucose during gestation maintained the same phenotype after themselves receiving fructose (10% wt/vol in drinking water) for three weeks, when adults.

## 2. Material and methods

### 2.1. Animals and experimental design

An animal model of maternal liquid fructose intake was developed as previously described (5, 6). Female Sprague-Dawley rats weighing 200-240 g were fed *ad libitum*, a standard rat chow diet (B&K Universal, Barcelona, Spain), and housed under controlled light and temperature conditions (12-h light-dark cycle; 22 ± 1°C). The experimental protocol was approved by the Animal Research Committee of the University San Pablo-CEU, Madrid, Spain (ref. number 10/206458.9/13).

1 Pregnant animals were randomly separated into a control group, a fructose-  
2 supplemented group (Fructose), and a glucose-supplemented group (Glucose) (five to  
3 six rats per group). Fructose and glucose were supplied as a 10% (wt/vol) solution in  
4 drinking water throughout gestation. The concentration used here (10% w/v) is very  
5 close to that of sugar-sweetened beverages (SSB). Control animals received no  
6 supplementary sugar. The total amount of ingested energy did not differ between  
7 fructose-fed, glucose-supplemented and control rats, as described in (5) and the amount  
8 of total calories obtained from simple sugars was around 25% for the fructose-group  
9 and 35% for the glucose-group (16). On gestational day 21, food was removed at 8 a.m.  
10 and pregnant rats were sacrificed two hours later. Plasma was obtained by blood  
11 centrifugation in Na<sub>2</sub>-EDTA tubes, aliquoted and stored at -80°C until analysis. Liver and  
12 adipose tissue were obtained, placed in liquid nitrogen and kept at -80 °C until analysis.  
13 The conceptus was dissected, and placentas and fetuses were collected. Placentas from  
14 the same litter were pooled and frozen. Fetuses (without being separated by gender)  
15 were decapitated. Blood from all pups of the same mother was collected and plasma  
16 was obtained in tubes containing Na<sub>2</sub>-EDTA. The livers of the fetuses were obtained, and  
17 those coming from the same mother were pooled and placed in liquid nitrogen to be  
18 frozen until processed for further analysis (5, 16).

19 Other set of pregnant rats was allowed to deliver and on the day of birth, each  
20 suckling litter was reduced to nine pups per mother. After delivery, both mothers and their  
21 pups were maintained with water and food *ad libitum*. At 21 days of age, pups were  
22 separated by gender and kept fed on a standard rat chow diet (B&K Universal, Barcelona,  
23 Spain) and water without additives. Animals within each experimental group were born  
24 to different dams to minimize the “litter effects”. At 240 days of age, one half of the  
25 male progeny was randomly separated. When the progeny was 261-days-old, it was  
26 sacrificed and blood and tissues were collected. Remarkably, these animals had received  
27 no subsequent additive in the drinking water for their entire lives (17).

28 The other half of the male progeny was subjected to the next protocol: First, they  
29 were weighed and an aliquot of plasma was obtained from the tail in order to confirm  
30 that the values between the experimental groups both for body weight and for several  
31 analytes (glucose, triglycerides, non-esterified fatty acids, etc) were similar (18). Later,  
32 independently from the experimental group of mothers to which they had been born,

1 they were maintained on solid pellets and supplied with drinking water containing 10%  
2 (wt/vol) fructose. Thus, three experimental groups were formed: C/F, F/F, G/F, the first  
3 letter indicating whether the mothers had been supplied during pregnancy with tap  
4 water (C, control), or water containing a carbohydrate (F: fructose; G: glucose); and the  
5 second letter indicating the period with fructose (F), when they were adults. When the  
6 progeny was 261-days-old, they were decapitated at 10 a.m. and blood collected using  
7 tubes containing Na<sub>2</sub>-EDTA. Prior to sacrifice, food was removed at 8 a.m. The period with  
8 fructose supplementation was selected to last 21 days (from 240 to 261 days of age) as  
9 previously described (18). Liver and lumbar and epididymal adipose tissues were  
10 immediately removed, placed in liquid nitrogen and kept at -80 °C until analysis. Samples  
11 were then centrifuged, and plasma was stored at -80 °C until processed for later  
12 determinations. In parallel, a fourth experimental group was used, C/C: male progeny  
13 from control mothers supplied with water without any additives when adult (18, 19).  
14 There was no difference in the total amount of ingested energy between fructose-fed rats  
15 and control (C/C) group (18) and, for the three groups of fructose-fed males (C/F; F/F, G/F),  
16 around 25% of the total amount of energy was acquired from fructose (18) and this is  
17 similar to the daily energy intake from simple sugars observed in heavy consumers of SSB  
18 in human populations (20-25%) (16).

## 2.2. Plasma determinations

39 Plasma H<sub>2</sub>S levels were measured with the methylene blue method as previously  
40 described with modifications (20). Briefly, 200 µL of plasma were deproteinized with  
41 150 µL 20% TCA. After centrifugation, 250 µL of supernatant were treated with 150 µL  
42 1% zinc acetate, 100 µL 20 mM N1,N1- dimethylbenzene-1.4-diamine sulfate  
43 (Fluorochem, UK) in 7.2 M HCl and 133 µL 30 mM FeCl<sub>3</sub> (Panreac AppliChem, IL, USA) in  
44 1.2 M HCl. Samples were then vortexed and incubated at room temperature for 20  
45 minutes and absorbance measured at 630 nm. A standard curve from 1.56 to 200 µM of  
46 sodium hydrosulfide (NaHS, Fluorochem, UK) was performed following the same  
47 procedure as with the samples.

### 2.3. Determination of H<sub>2</sub>S production in liver, adipose tissue and placenta

H<sub>2</sub>S production in liver, lumbar and epididymal adipose tissue and placenta was evaluated following the Lead Sulfide method as previously described with modifications (21). Briefly, tissues were homogenized in Phosphate-buffered saline (PBS) and their protein levels measured with the BCA Assay Kit (Thermo Fisher, MA, USA). One hundred to 300 µg of protein were incubated at 37°C in the presence of 10 mM Cys (Sigma-Aldrich, MO, USA) or 30 mM Hcy (Fluorochem, UK), and 20 µM Pyridoxal 5'-phosphate (PLP, Sigma-Aldrich, MO, USA) (for livers) or 2 mM PLP (for adipose tissue and placenta) on 96 well plates covered with a lead acetate (II) membrane. Incubations were performed until dots of lead sulfide were detected but not saturated, and this occurred after 2 h for liver, 6 h for adipose tissue and 3 h for placenta. In order to prepare these membranes, Whatman n° 2 paper was soaked into 20 mM lead acetate (Sigma-Aldrich, MO, USA) and vacuum dried. Dots were densitometered (BioRad Densitometer G-800, CA, USA) for quantification. A standard curve from 0 to 1000 mM NaHS was performed for each membrane.

### 2.4. RNA extraction and gene expression determination by qPCR

Total RNA was isolated from liver or placenta using Ribopure (Invitrogen, ThermoFisher Scientific, USA). Total RNA was subjected to DNase I treatment using Turbo DNA-free (Invitrogen, ThermoFisher Scientific, USA), and RNA integrity was confirmed by agarose gel electrophoresis. Afterwards, cDNA was synthesized by oligo(dT)-primed reverse transcription with Superscript II (Invitrogen, ThermoFisher Scientific, USA). qPCRs were performed using a Light Cycler 1.5 (Roche, Germany). The reaction solution was carried out in a volume of 20 µl, containing 10 pmol of both forward and reverse primers, 10x SYBR Premix Ex Taq (Takara Bio Inc., Japan) and the appropriate nanograms of the cDNA stock. Rps29 was used as a reference gene for qPCR. The primer sequences were obtained either from the Atlas RT-PCR Primer Sequences (Clontech, CA, USA) or designed using Primer3 software (University of Massachusetts Medical School, MA, USA) (22). Samples were analysed in duplicate on each assay. Amplification of non-specific targets was discarded using the melting curve analysis method for each amplicon. qPCR efficiency and linearity were assessed by optimization

1  
2 of the standard curves for each target. The transcription was quantified with Light Cycler  
3 Software 4.05 (Roche, Germany) using the efficiency correction method (23).  
4

## 5 6 2.5. Statistical Analysis 7

8  
9 Results were expressed as means  $\pm$  S.E. Treatment effects were analyzed by one-  
10 way analysis of variance (ANOVA). When treatment effects were significantly different  
11 ( $P < 0.05$ ), means were tested by Tukey's multiple range test, using the computer  
12 program SPSS (version 23). When the variance was not homogeneous, a *post hoc*  
13 Tamhane test was performed.  
14  
15  
16  
17

## 18 19 20 21 3. Results 22

### 23 24 3.1. Carbohydrate intake during pregnancy decreases H<sub>2</sub>S production in 25 liver and placenta, but not in lumbar adipose tissue. 26

27  
28 Hydrogen sulfide is a gasotransmitter produced in the transsulfuration pathway  
29 with proved beneficial effects in many metabolic diseases. However, plasma H<sub>2</sub>S levels  
30 hardly changed in pregnant rats after fructose or glucose consumption throughout  
31 gestation ( $11.90 \pm 0.78$ ;  $11.84 \pm 0.28$ ;  $10.94 \pm 0.38$   $\mu$ M for control, fructose-, and glucose-  
32 fed mothers, respectively). Surprisingly, H<sub>2</sub>S production in the liver presented a  
33 significant decrease in the two groups of rats that consumed any liquid carbohydrate  
34 during gestation in comparison to the control dams (Figure 1A). This organ is the main  
35 producer of H<sub>2</sub>S in the organism (24). However, the expression of the three main  
36 enzymes involved in the transsulfuration pathway did not display significant differences  
37 (Table 1) in this tissue, although CSE gene expression did show a tendency to decrease  
38 in fructose-fed pregnant rats. The results obtained in plasma could be related to other  
39 tissues that are known to produce this gasotransmitter, although at a lower level, such  
40 as adipose tissue (10). In fact, H<sub>2</sub>S production in lumbar adipose tissue (Figure 1B) did  
41 show a trend to be increased in the two carbohydrate-consuming groups, becoming  
42 almost significant when fructose-fed pregnant rats were compared to control rats ( $P =$

In order to evaluate the importance of the placenta in the production of H<sub>2</sub>S during gestation, both synthesis of H<sub>2</sub>S and transsulfuration enzymes gene expression were measured. In accordance with the findings observed in liver, placental H<sub>2</sub>S production was also diminished in carbohydrate-fed dams (Figure 1C), becoming significant in fructose-fed pregnant rats and almost significant (P = 0.093) in glucose-fed mothers, in comparison to the control rats. As shown in Table 1, CBS gene expression presented an increase in placenta of fructose-fed pregnant rats and it was significant when compared to glucose-fed mothers. On the other hand, CSE and 3MST gene expression did not show significant changes between the three experimental groups (Table 1). Nevertheless, gene expression of the three enzymes of the transsulfuration pathway in placenta displayed lower levels than in liver.

As fructose is able to cross the placenta and it can also be produced there (25), all these changes observed after carbohydrate consumption during gestation could also be affecting the fetuses. Thus, H<sub>2</sub>S production and transsulfuration enzymes gene expression were evaluated. In accordance with the findings found in maternal liver and placenta, H<sub>2</sub>S production in the liver of fetuses from carbohydrate-fed mothers tended to be decreased when compared to those from control dams (Figure 1D), although without becoming significantly different. However, neither CBS nor CSE or 3MST gene expression presented changes in liver of fetuses from fructose-, glucose-fed or control mothers (Table 1).

### 3.2. Carbohydrate ingestion during gestation produces changes in the transsulfuration pathway in adult male offspring.

Bearing in mind the results observed in the liver of fetuses from fructose- or glucose-fed mothers, we wanted to evaluate if these changes were maintained in male offspring from carbohydrate-fed dams when adult. As shown in Figure 2A, H<sub>2</sub>S production in the liver presented a non-significant decrease in males from fructose- or glucose-fed mothers, in consonance with the effects found in fetal liver (Figure 1D). Plasma H<sub>2</sub>S levels were reduced in males from glucose-supplemented mothers in comparison to the other two groups (14.53 ± 2.11; 14.61 ± 0.21; 12.53 ± 0.55 μM for males from control, fructose- and glucose-fed dams, respectively; P < 0.05, glucose vs.

1 fructose). When gene expression was measured in the liver of male descendants, CBS  
2 did show a significant increase in male offspring from glucose-fed mothers compared to  
3 control and fructose groups, and 3MST displayed higher and significant gene expression  
4 in male progeny from carbohydrate-fed mothers versus control offspring (Table 2). This  
5 result could be in contrast with the findings observed for H<sub>2</sub>S production in the liver but  
6 CSE, the main enzyme involved in transsulfuration pathway in the liver (26), did show a  
7 slight reduction in males from fructose-fed mothers, although this did not become  
8 significant (Table 2). On the other hand, although lumbar (Figure 2B) adipose tissue did  
9 not present significant changes in H<sub>2</sub>S production between the three groups, epididymal  
10 fat pads displayed a non-significant trend to be increased in progeny from carbohydrate-  
11 fed rats in comparison to the control group (Figure 2C).

### 23 3.3. Fructose consumption in male adult rats causes a maternal-intake 24 dependent reduction in H<sub>2</sub>S production in liver and adipose tissue.

27 After evaluating the transsulfuration pathway in adult male descendants from  
28 carbohydrate-fed mothers, we wanted to discover if that phenotype was conserved by  
29 exposing male offspring from control, fructose- or glucose-fed mothers to a fructose  
30 consumption and to check if maternal diet influences the response to this fructose  
31 exposure.

37 Plasma H<sub>2</sub>S levels were not affected by fructose ingestion, although they tended to  
38 be higher, but not significantly, independently of the maternal consumption ( $13.34 \pm 0.63$ ;  
39  $17.72 \pm 3.08$ ;  $22.22 \pm 2.81$ ;  $25.06 \pm 5.42$   $\mu\text{M}$  for C/C, C/F, F/F and G/F, respectively).  
40 Surprisingly, the hepatic production of this gasotransmitter did seem to present the  
41 opposite result to that of plasma data, as shown in Figure 3A. H<sub>2</sub>S production was  
42 diminished in the liver of male offspring from control, fructose- and glucose-fed mothers  
43 after fructose intake (Figure 3A), this reduction being more pronounced in F/F group. In  
44 fact, the effect became almost significant when F/F was compared to G/F group ( $P = 0.065$ ).  
45 Moreover, these findings were corroborated when H<sub>2</sub>S production was measured using  
46 Hcy as a substrate. It is well known that CSE and CBS use Cys as substrate, whereas Hcy is  
47 substrate only for CSE (26). Interestingly, the same results obtained for H<sub>2</sub>S synthesis from  
48 Cys (Figure 3A) were observed when Hcy was used as a substrate of the reaction (Figure  
49

3B). In order to evaluate if these changes were caused by modifications in the transsulfuration pathway enzymes, CBS, CSE and 3-MST gene expression were measured. None of these enzymes presented significant changes in its gene expression (Table 3), although CSE, the main enzyme involved in H<sub>2</sub>S production in the liver (26), tended to be decreased in liver from males that consumed fructose when adult and which mothers had ingested water (C/F) or liquid fructose (F/F) during gestation. Interestingly, H<sub>2</sub>S production in adipose tissue responded to the fructose supplementation in a maternal-intake dependent manner. Thus, both lumbar (Figure 3C) and epididymal adipose tissues (Figure 3D) displayed a fructose-induced significant reduction in H<sub>2</sub>S production in male descendants from fructose (F/F) and glucose (G/F) fed mothers, but not in C/F, when compared to C/C group.

#### 4. Discussion

In the last decades, obesity, MetS, CVD and diabetes have escalated to epidemic proportions in many countries worldwide (27). The DOHaD theory has linked maternal nutrition to the risk of suffering metabolic diseases in descendants when adult. According to this, early life (pre- and post-natal) nutrition would produce molecular adaptations in pups that will predispose them to a higher risk of metabolic disturbances in later life (3, 28). Consumption of SSB and processed foods has increased in recent years and many studies have established a relationship between their consumption and the development of metabolic diseases (17, 29, 30).

H<sub>2</sub>S is a gasotransmitter whose reduction in plasma has been related to obesity and type 2 diabetes and it seems to protect against the pathogenesis of atherosclerosis (31). Therefore, our goal in the present study is to investigate whether maternal fructose leads to changes in the transsulfuration pathway, which produces H<sub>2</sub>S, in their pups and if these modifications, if any, are preserved later, when adult. In the present study, neither fructose- nor glucose-fed mothers presented changes in their H<sub>2</sub>S plasma levels, however a significant reduction in the production of this gasotransmitter was observed both in liver and in placenta. This discrepancy between H<sub>2</sub>S plasma levels and its production in liver has been previously reported by Peh et al, but using a high fat diet (32), and they proposed that it could be caused by H<sub>2</sub>S produced in non-hepatic tissues

1 (33), such as adipose tissue, kidney or gut. In fact, lumbar adipose tissue presented in  
2 our carbohydrate-fed mothers a non-significant increase in the H<sub>2</sub>S production. In  
3 contrast to Peh et al (32), we did not observe significant changes in the gene expression  
4 of the transsulfuration pathway enzymes in neither liver nor placenta. Nevertheless,  
5 modifications in H<sub>2</sub>S synthesis have been related not only with the gene expression of  
6 transsulfuration pathway but also with the activity of these enzymes (34). Moreover,  
7 H<sub>2</sub>S has been inversely related to oxidative stress (34) and, in a previous report, we have  
8 showed an imbalanced redox status in these carbohydrate-fed pregnant rats (16).  
9

10 We and others have demonstrated that maternal fructose produces profound  
11 molecular and metabolic changes in the fetuses (5, 16, 29), but there are no studies that  
12 evaluate its relationship with imbalances in the transsulfuration pathway in the  
13 offspring. Our findings indicate a slight reduction in H<sub>2</sub>S production in the liver of fetuses  
14 from fructose- and glucose-fed mothers and, interestingly, this diminution induced by  
15 maternal carbohydrate intake was maintained in male descendants when adult. These  
16 results would indicate an example of fetal programming in the offspring. In fact, we have  
17 recently demonstrated that maternal fructose is able to modify the methylation state of  
18 gene promoters of key proteins in cholesterol metabolism in the adult progeny (35).  
19

20 Bearing in mind that epigenetic modifications can cause different responses to  
21 environmental factors (36), we have demonstrated that the fructose-induced  
22 diminution in H<sub>2</sub>S production observed here in liver and adipose tissue of male rats is a  
23 maternal nutrition-dependent effect. Beneficial effects of H<sub>2</sub>S in cardiovascular events  
24 have been widely studied (37, 38), so a reduction in the gasotransmitter levels could be  
25 one of the links between fructose consumption and symptoms of CVD and MetS. In fact,  
26 we have previously reported that fructose intake provokes characteristic features of  
27 MetS, such as oxidative stress and lipid abnormalities, in the adult offspring and that  
28 these imbalances are influenced by maternal intake of carbohydrates (18, 19). However,  
29 H<sub>2</sub>S plasma levels were not reduced by fructose consumption independently of that had  
30 been taken by their mothers. Therefore, more specific studies are needed to connect  
31 the diminution in H<sub>2</sub>S production, H<sub>2</sub>S plasma levels and characteristics of MetS  
32 observed in our rats. Nevertheless, as mentioned above, other tissues that can also  
33 produce H<sub>2</sub>S could be involved (32). In addition, reductions in H<sub>2</sub>S production have been  
34 related to insulin resistance in adipose tissue (10) and, interestingly, our animals which

1 were fed liquid fructose showed such a decrease. We were not able to detect systemic  
2 insulin resistance in these male rats (18), but it could possibly exist locally, in adipose  
3 tissue.  
4

5 The administration of food containing 75% fructose in rats conducted to a reduction  
6 in CSE levels in thoracic aortas producing an impaired endothelium-dependent  
7 vasorelaxation (39) has been described and, further, a diet with 65% fructose did lead  
8 to oxidative stress and insulin resistance in rats with decreased levels of H<sub>2</sub>S in plasma  
9 (40). In the present study, we reported similar alterations in the transsulfuration  
10 pathway both in liver and adipose tissue but using a much lower fructose amount (10%  
11 w/v). The reduction in H<sub>2</sub>S production observed here in the liver could be due to a  
12 diminished CSE, the main transsulfuration enzyme (26), gene expression in C/F and F/F  
13 groups, but not in G/F. Nevertheless, since H<sub>2</sub>S is generated from HCy (41), this reduction  
14 of H<sub>2</sub>S production could possibly be related to lower plasma levels of HCy which we have  
15 found in the three groups that received fructose (data not shown). Furthermore,  
16 modifications described here in H<sub>2</sub>S synthesis could also be due to changes in activity of  
17 the enzymes in the transsulfuration pathway, where fructose would be affecting it  
18 directly or indirectly through diverse factors such as calcium, oxidative stress, hormones  
19 or glucose (34). Interestingly, the effects observed here for H<sub>2</sub>S in liver and adipose  
20 tissue are probably more relevant than if we had found them in plasma (32). Whereas  
21 plasma H<sub>2</sub>S levels are the sum of production from many tissues, H<sub>2</sub>S synthesis is key in  
22 the functioning of the tissue. This would be the situation for, among others, the aorta  
23 and relaxation of endothelium, the adipose tissue and insulin sensitivity, the kidney and  
24 blood pressure, and the placenta and preeclampsia (10, 39, 42, 43). In fact, although we  
25 did not see changes in plasma H<sub>2</sub>S levels, the fructose-induced modifications in tissue  
26 production of H<sub>2</sub>S found here would parallel the low levels of plasma urea (38.5 ± 0.42;  
27 20.9 ± 0.90; 28.9 ± 2.1; 30.5 ± 2.4 mg/dL for C/C, C/F, F/F and G/F, respectively; P < 0.05,  
28 C/C vs. C/F and F/F; P < 0.05, C/F vs G/F). Since it is known that ammonia, produced  
29 along with the H<sub>2</sub>S in the transsulfuration pathway, participates in the synthesis of urea,  
30 these results observed for urea are confirmatory of the reduced transsulfuration  
31 pathway after a fructose intake.

57 In summary, this study shows in pregnancy that a fructose-rich diet *per se* or  
58 situations producing an impaired insulin sensitivity such an excessive intake of glucose  
59  
60  
61  
62  
63

65

1 (5) generate a clear diminution in the hepatic and placental production of H<sub>2</sub>S. And this  
2 effect is observed not only in pregnant mothers, but also in male offspring (both in fetal  
3 and in adult stages) and, mainly, when their offspring are themselves subjected to a high  
4 fructose intake. Interestingly, these results correlate with others published where  
5 proatherogenic diets also caused H<sub>2</sub>S depletion (32, 33, 40, 44). Given this  
6 gasotransmitter has been proposed as a possible treatment for CVD and as a protective  
7 factor in developing MetS alterations (37), the importance of these findings lies in the  
8 escalating worldwide intake of SSBs and its, increasingly clearer, relationship with non-  
9 communicable diseases (2, 45). Altogether, the clinical significance of the  
10 transsulfuration pathway studies and its connection with fructose intake should be  
11 taken into consideration.

## Figure Legends

**Figure 1:** Carbohydrate (fructose or glucose) consumption during pregnancy affects H<sub>2</sub>S production in the liver and placenta of pregnant rats, but not adipose tissue. A) Hepatic H<sub>2</sub>S production and membrane showing lead acetate precipitates formed in the assay. Darker precipitates indicate higher H<sub>2</sub>S production in the tissue. B) Lumbar adipose, C) Placental and D) Fetal hepatic H<sub>2</sub>S production of control (empty bar), fructose-fed (grey bar) or glucose-fed (black bar) pregnant rats. Data are means ± S.E. from 6-7 litters. Values not sharing a common letter are significantly different ( $P < 0.05$ ).

**Figure 2:** Carbohydrate intake during pregnancy influences H<sub>2</sub>S production in the liver and adipose tissue of male offspring. A) Hepatic, B) lumbar and C) epididymal adipose tissues H<sub>2</sub>S production of 261-day-old male progeny from control (empty bar), fructose-fed (grey bar) and glucose-fed (black bar) pregnant rats. Data are means ± S.E. from 5-6 litters. Values not sharing a common letter are significantly different ( $P < 0.05$ ).

**Figure 3:** Maternal carbohydrate intake differentially affects fructose-induced diminution of H<sub>2</sub>S production in the progeny. A) Hepatic H<sub>2</sub>S production from Cys and membrane showing lead acetate precipitates formed in the assay. Darker precipitates indicate higher H<sub>2</sub>S production in the liver. B) Hepatic H<sub>2</sub>S production from H<sub>2</sub>Cys. C) Lumbar and Epididymal adipose tissues H<sub>2</sub>S production of control (CF, light grey bar), fructose- (FF, black bar), and glucose-supplemented (GF, dark grey bar) mothers. C/C: Control 261-day-old male offspring from control pregnant rats (empty bar, C/C). Data are means ± S.E. from 5-6 litters. Values not sharing a common letter are significantly different ( $P < 0.05$ ). Cys: cysteine. H<sub>2</sub>Cys: homocysteine.

| CSE (a.u.)                       | 0,069 ± 0,011              | 0,097 ± 0,013               | 0,099 ± 0,023              |
| 3-MST (a.u.)                     | 0,715 ± 0,033              | 0,793 ± 0,092               | 0,672 ± 0,046              |

M ± SE, n = 5-6 pregnant rats; n = 5-6 liver pools of the fetuses of the same litter; n = 5-6 placental pools of the same litter. Different letters indicate significant differences between the groups ( $P < 0.05$ ). Relative target gene mRNA levels were measured by Real Time PCR, as explained in Materials and Methods, and normalized to Rps29 levels and expressed in arbitrary units (a.u.). CBS: cystathionine beta-synthase; CSE: cystathionine gamma-lyase; 3-MST: 3-mercaptopyruvate sulfurtransferase.

**Table 2**

Liver gene expression (mRNA) of the transsulfuration pathway of 261-day-old male progeny from fructose- or glucose-supplemented and control mothers

|              | <b>Control</b>           | <b>Fructose</b>          | <b>Glucose</b>            |
|--------------|--------------------------|--------------------------|---------------------------|
| CBS (a.u.)   | 3,29 ± 0,97 <sup>a</sup> | 3,85 ± 0,92 <sup>a</sup> | 7,61 ± 0,53 <sup>b</sup>  |
| CSE (a.u.)   | 163,4 ± 21,1             | 115,7 ± 24,8             | 160,5 ± 9,8               |
| 3-MST (a.u.) | 6,70 ± 0,66 <sup>a</sup> | 9,24 ± 0,54 <sup>b</sup> | 10,24 ± 0,13 <sup>b</sup> |

Data are M ± SE, male rats from 5-6 litters. Relative target gene mRNA levels were measured by real time PCR, as explained in Materials and Methods, and normalized to Rps29 levels and expressed in arbitrary units (a.u.). Different letters indicate significant differences between the groups (P < 0.05). CBS: cystathionine beta-synthase; CSE: cystathionine gamma-lyase; 3-MST: 3-mercaptopyruvate sulfurtransferase.

**Table 3**

Liver gene expression (mRNA) of the transsulfuration pathway of 261-day-old fructose-fed male progeny from fructose-fed (F/F) or glucose-supplemented (G/F) and control mothers (C/F)

|              | C/C          | C/F          | F/F          | G/F          |
|--------------|--------------|--------------|--------------|--------------|
| CBS (a.u.)   | 3,20 ± 0,60  | 2,06 ± 0,40  | 3,75 ± 1,29  | 2,35 ± 0,26  |
| CSE (a.u.)   | 151,8 ± 15,8 | 125,1 ± 22,1 | 128,2 ± 20,3 | 168,9 ± 12,3 |
| 3-MST (a.u.) | 6,70 ± 0,66  | 6,65 ± 0,89  | 7,44 ± 0,64  | 8,52 ± 0,41  |

Data are M ± SE, males from five to six litters. C/C: Control male offspring of control dams. Relative target gene mRNA levels were measured by real time PCR, as explained in Materials and Methods, and normalized to Rps29 levels and expressed in arbitrary units (a.u.). Different letters indicate significant differences between the groups (P < 0.05). CBS: cystathionine beta-synthase; CSE: cystathionine gamma-lyase; 3-MST: 3-mercaptopyruvate sulfurtransferase.
